Abstract

Objective—Body mass index (BMI) is a widely used indicator of obesity status in clinical settings and population health research. However, there are concerns about the validity of BMI as a measure of obesity in post-menopausal women. Unlike BMI, which is an indirect measure of obesity and does not distinguish lean from fat mass, dual energy x-ray absorptiometry (DXA) provides a direct measure of body fat and is considered a gold standard of adiposity measurement. The goal of this study is to examine the validity of using BMI to identify obesity in post-menopausal women relative to total body fat percent measured by DXA scan.

Methods—Data from 1329 post-menopausal women participating in the Buffalo OsteoPerio study were used in this analysis. At baseline, women ranged in age from 53 years to 85 years. Obesity was defined as BMI >30kg/m² and body fat percent (BF%) greater than 35%, 38% or 40%. We calculated sensitivity, specificity, positive predictive value and negative predictive value to evaluate the validity of BMI defined obesity relative BF%. We further explored the validity of BMI relative to percent body fat using graphical tools, such as scatterplots and receiver operating characteristic (ROC) curves. Youden's J index was used to determine the empirical optimal BMI cut point for each level of BF% defined obesity.

Results—The sensitivity of BMI-defined obesity was 32.4% for 35% body fat, 44.6% for 38% body fat and 55.2% for 40% body fat. Corresponding specificity values were 99.3%, 97.1% and 94.6%, respectively. The empirical optimal BMI cut-point to define obesity is 24.9kg/m² for 35% BF, 26.49 kg/m² for 38% BF and 27.05 kg/m² for 40% BF according to the Youden Index.

Conclusions—Results demonstrate that a BMI cut-point of 30 kg/m² does not appear to be an appropriate indicator of true obesity status in post-menopausal women. Empirical estimates of the

obesity; postmenopausal women; validation study; BMI; body fat

Introduction

Over the past three decades, the prevalence of obesity has increased substantially across all age groups.^{1,2} Although the effect of obesity on morbidity and mortality in childhood and middle age has been studied extensively, there is still a debate about the health risks of obesity at older ages.^{3–5} Questions about the effect of obesity in older adults are particularly salient in postmenopausal women because in the years following the menopausal transition women often experience changes in body composition.^{6–8} Before it is possible to answer questions about the effect of obesity in postmenopausal women, it is crucial to empirically validate tools to measure excess body weight in this population.

Body mass index (BMI) is the most widely used indicator of obesity status in clinical settings and population health research. According to the World Health Organization, BMI greater than 30kg/m² is considered obese. Despite its widespread use in the general population, several authors have questioned whether BMI is a valid measure of obesity status in older adults.^{9–11} Prior studies indicate that BMI may be particularly limited as a measure of obesity status in older adults.^{12,13} BMI is an indirect measure of adiposity, and does not account for the location of adipose tissue (e.g., subcutaneous vs. visceral fat), differentiate between fat mass or lean mass, or account for variation in body composition.^{11,14,15}

Concerns about the validity of BMI to correctly categorize obesity status may be amplified in older women. It is well documented that significant physical changes occur in the postmenopausal period, including body weight changes, redistribution of adipose tissue, decreased skeletal muscle mass, and loss of height.^{16–18} Evidence suggests that menopause contributes to a change in body composition, such as an accumulation of visceral fat, irrespective of body weight change.^{17,19} As an example, consider a woman who loses height as she ages. Since BMI is a ratio of weight-for-height, age-related height loss would result in an increased BMI value by virtue of decreasing the value of the denominator, even if body weight remained constant.¹⁸ Additionally, post-menopausal women lose bone mineral density over time, which may lead to reduced overall body weight, smaller numerator and overall BMI value, even if the amount of fat mass remains the same.²⁰ Considering the changes in body composition that occur as part of the natural aging process, it is unlikely that BMI corresponds to the same degree of adiposity in young or middle aged women and older postmenopausal women and use of BMI in this population may result in misclassification of obesity status and an inaccurate representation of obesity-related risks.¹⁸

Aside from BMI, there are several other indirect measures of adiposity that are often reported in the literature, such as waist circumference and waist to hip ratio, but each has its own set of limitations. Ultimately, no indirect measure of adiposity is able to differentiate

between adipose tissue, lean body mass, and bone mass. Direct measures of adiposity, such as dual energy x-ray absorptiometry (DXA) scan, provide a much more accurate measurement of body fat, but require access to expensive specialized equipment and skilled technicians.^{21,22} Validation studies have indicated that body fat percent (BF%) from DXA scan is an appropriate reference standard, or gold standard, for the measurement of adiposity.^{12,21–23}

The objective of the present study is to explore the relationship between BMI and percent body fat (BF%) in post-menopausal women and examine the validity of using a BMI cut-point of 30kg/m² to identify obesity in post-menopausal women relative to body fat percentage (BF%) measured by DXA scan.

Methods

Study data

Participants were 1329 post-menopausal women aged 53–85 years in the Buffalo OsteoPerio study, an ancillary study to the Women's Health Initiative (WHI).²⁴ All OsteoPerio participants were also in the WHI observational study and recruited from the WHI Buffalo Clinical Center.²⁴ Between 1997 and 2000, participants completed baseline OsteoPerio questionnaires and visited the clinical center for anthropometric measures, including weight and height, as well as a dual energy x-ray absorptiometry (DXA) scan with a Hologic QDR-4500A dual x-ray bone densitometer (Hologic Inc, Bedford, MA). Participants returned for 5-year follow-up visits from 2002 to 2005 (n=1,013) and 17-year follow-up is currently underway (n=390 available for the present analysis). Six participants were missing BMI (1) or BF% (5). Anthropometric measures and DXA scans were measured at baseline and repeated at follow-up visits. This analysis includes data collected at both baseline and follow-up visits, resulting in an analytic cohort of 2726 observations.

Whole body DXA scan was used to measure body composition (fat mass, fat distribution, lean mass) as well as total body and site-specific bone density (hip, spine, wrist). Positioning and analysis of DXA scan results were performed according to standard protocol by trained technicians. Prior to the scan, participants were asked to change into medical gowns and asked to remove all jewelry.²² The validity and precision of the DXA measurements used in the WHI study has been reported elsewhere.²² Chen and colleagues demonstrated that DXA-derived measures of fat mass are highly correlated with results from MRI scan (fat mass: Pearson's correlation coefficient=0.94; lean mass: Pearson's correlation coefficient=0.99).^{16,22} From the DXA scan, whole body fat percentage was calculated as total body fat mass over total mass multiplied by 100.^{25,26}

Body Mass Index

Measured height and weight were used to calculate BMI. Having a BMI value greater than 30 kg/m² indicates obesity, while individuals with BMI value less than 30 kg/m² are considered non-obese.⁸ This cut point is widely accepted in the biomedical literature to define obesity and also is used in clinical settings. It has been endorsed by the World Health

Organization, Centers for Disease Control, National Institutes of Health, and various other disease-specific organizations.^{8,27–29}

Percent body fat (BF%)

Unlike BMI, there is a lack of consensus regarding a cut point that should be used to define obesity according to BF%. In women, a BF% greater than 35% is frequently used as the cut point to define obesity, but this is largely based on expert opinion and repeated use in the published literature rather than scientific evidence that 35% is a meaningful cutoff value.^{9,12} The 1995 WHO Technical Report that created the BMI threshold for obesity does not make a recommendation about the BF% that should be used to define obesity.^{8,30,31} Published cut points to define obesity according to BF% in women range from 25% to 40%.^{13,32,33} Considering the absence of a well-established BF% cut-point to classify postmenopausal women as obese, we will examine 35%, 38% and 40% BF from DXA scan as the reference standard to define obesity.

Statistical analysis

In the current analysis, we compared obesity defined by BMI ($<30 \text{ kg/m}^2$ vs. 30 kg/m^2) with obesity defined by BF% (35%, 38% and 40%). Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were calculated to assess the diagnostic accuracy of BMI-defined obesity compared with obesity defined by BF%. Further description of calculations is provided in Supplemental Digital Content file 1. Sensitivity, specificity, PPV and NPV are all proportions that are calculated from counts of true positives (TP), false negatives (FN), true negatives (TN), and true negatives (TN). Sensitivity ($\Pr(X^*=1|X=1)$) is defined as the proportion of individuals that are truly obese ($X^*=1$) and classified as obese by BMI ($X=1$). It is calculated as $\text{Se} = \text{TP}/(\text{TP} + \text{FN})$. Specificity ($\Pr(X^*=0|X=0)$) is defined as the proportion of individuals that are truly non-obese ($X^*=0$) and classified as non-obese by BMI ($X=0$), calculated as $\text{Sp} = \text{TN}/(\text{TN} + \text{FP})$. Positive predictive value ($\Pr(X=1|X^*=1)$) is the probability that someone who is classified as obese by BMI is truly obese, calculated as $\text{PPV} = \text{TP}/(\text{TP} + \text{FP})$, and negative predictive value ($\Pr(X=0|X^*=0)$) is the probability that someone classified as non-obese is truly non-obese, calculated as $\text{NPV} = \text{TN}/(\text{TN} + \text{FN})$. To account for the correlation between observations, pooled logistic regression was used to provide a valid estimate of the 95% confidence interval for sensitivity, specificity, PPV and NPV values. Percent correctly classified is the proportion of women who were classified as true positives and true negatives divided by the total population, calculated as $(\text{TP} + \text{TN})/(\text{TP} + \text{TN} + \text{FP} + \text{FN})$. The area under the curve (AUC) was calculated as a metric to evaluate the discriminatory ability of a BMI cut point of 30 kg/m^2 , a higher AUC value indicates a stronger discrimination ability while an AUC equal to 0.5 means that BMI is no better than chance at identifying individuals according to their true obesity status.³⁴

Scatterplots were used to graphically explore the validity of BMI as a continuous variable against continuous BF%. Comparing Figure 1a and 1b additionally provides a basis for exploring the effect of changing BF% cut points on the prevalence of obesity and the number of women who are correctly, or incorrectly, classified.

Finally, although BMI 30 kg/m^2 is well accepted as the cut point to define obesity according to BMI, we investigated the empirical optimal BMI cut point for each level of BF % defined obesity (35%, 38% and 40%). This analysis demonstrates the BMI cut point that should be used to maximize the sum of sensitivity and specificity at each BF% cut point. The Youden Index (also known as Youden's J statistic) was used to determine the optimal threshold value for BMI.^{35,36} For all possible threshold values (t), the Youden Index is defined as:

$$J = \left(\max_t \right) [\text{sensitivity}(t) + \text{specificity}(t) - 1]$$

The critical threshold value, t^* , is the point at which the sensitivity and specificity is maximized.³⁶ We subsequently created a Receiver Operating Characteristic (ROC) curve of sensitivity versus 1-specificity for each of the BF% cut points and plotted the optimal BMI cut point on the respective ROC graphs.^{34,37} All analyses were conducted with Stata 14 Software. Annotated software code is provided (see Supplemental Digital Content 2) to facilitate greater understanding of the results presented here.

Results

Table 1 presents descriptive characteristics of the study cohort. The mean BMI of the participants was 26.7 kg/m^2 (SD=5.2, range: 15.4–57.4 kg/m^2) and mean BF% was 36.8% (SD=6.0, range: 14.4–54.1%). At baseline, average age was 66.1 years (SD=7.0). The sample was predominantly composed of white women. Based on BMI classification, 35% of the participants were classified as overweight and 21% were obese. There was a positive increase in percent body fat as BMI category increased; for the underweight, normal weight, overweight, and obese categories, the mean percent body fat values were 22.7%, 32.6%, 38.5%, and 43.4%, respectively.

Results presented in Table 2 demonstrate the validity of using BMI-defined obesity (BMI 30 kg/m^2) relative to referent standards of 35%, 38% and 40% BF. Using a BMI cut-point of 30 kg/m^2 , sensitivity and specificity ranged from 32.4% and 99.3% for 35% BF to 44.6% and 97.1% for 38% BF and 55.2% and 94.6% for 40% BF. These results demonstrate the low sensitivity of using 30 kg/m^2 to correctly identify an individual's true obesity status according to BMI. Even with 40 BF% as the reference criterion to define obesity according to BF%, only half of women (55%) who are truly obese are being identified as obese according to BMI. Increasing the BF% used as the referent standard from 35% to 40% produces a noticeable increase in sensitivity (+23%) at the expense of a moderate decrease in specificity (−4.6%). The NPV demonstrated the most notable change when comparing across levels of BF%, from 43.6% for 35% BF and 81.8% for 40% BF, indicating a 38% increase in the probability that someone who is truly non-obese is classified as non-obese by BMI.

Changing the BF% cut point used to define obesity has a substantial impact on the prevalence of the study population defined as obese; as the cut point increases, the proportion of women categorized as obese decreases. Using a cut point of 35% BF to define

obesity, the prevalence of obesity was 66% in the study sample, using a cut point of 38% BF resulted in 45% of women being categorized as obese, and using a cut point of 40% BF resulted in 32% being considered obese.

The scatterplots presented in Figure 1a and 1b are a visual representation of the degree of misclassification present when using BMI 30kg/m^2 to define obesity against varying BF% cut points. Figures 1a and 1b depicts the relationship between BMI and BF% as continuous variables. Quadrant A represents individuals who were defined as obese by BMI but non-obese by BF% (upper left), quadrant B represents individuals who were classified as obese by BMI and BF% (upper right), quadrant C represents individuals who were non-obese by BMI and BF% (lower left), and quadrant D represents individuals who were classified as non-obese by BMI and obese by BF% (lower right). Participants in quadrants A and D are considered misclassified (i.e., false positive or false negatives), while participants in quadrants B and C are considered correctly classified (i.e., true positive or true negative).. In Figure 1a, a cut point of 35% BF is used to define obesity and in Figure 1b a cut point of 40% BF is used to define obesity, indicated by the black vertical lines at 35 and 40 percent body fat on the respective graphs. In both Figures 1a and b, BMI greater than 30 kg/m^2 is used to define obesity, indicated by the black horizontal line on each graph. The fitted line demonstrates a quadratic relationship between BMI and BF%. Upon visual inspection, it is clear that a greater proportion of the sample is considered obese using a cut point of 35% BF rather than 40% BF. A scatterplot demonstrating the cut point of 38% is presented in Supplemental Digital Content 3. Figures 1a and b provide information about the concordance between BMI-defined obesity and % BF-defined obesity. Using a cut point of 35% BF to define obesity, 55% of women were correctly classified by BMI and BF% and using a cut point of 40% BF results in 82% of women being correctly classified. In Figure 1a, the greatest proportion of women (44%) are in Quadrant D, and therefore misclassified, while in Figure 1b the greatest proportion of women (64%) are in Quadrant C, meaning they are correctly classified.

Further analyses (Table 3) demonstrated that the optimal cut point to define obesity using BMI is 24.84 kg/m^2 if 35% BF is considered the true referent standard to define obesity, a cut point of 26.49 kg/m^2 if 38% BF is considered the true referent standard, and a cut point of 27.04 kg/m^2 if 40% BF is the true referent standard. Using the empirical optimal BMI cut point for each of the BF% levels results in over 80% of women being correctly classified. The ROC curves of sensitivity versus 1-specificity comparing the BF% cut points (e.g., 35%, 38% and 40%) and BMI can be found in Figure 2a–c. The optimal BMI cut point for each BF% is indicated on the respective ROC curves.

Discussion

The results of the present study indicate that a substantial proportion of older women who are truly obese are misclassified as non-obese by BMI, regardless of the BF% used as the reference standard. It is important for researchers and clinicians to recognize the substantial misclassification that may result from using BMI 30kg/m^2 as a criterion to define obesity in postmenopausal women. BMI additionally underestimates the prevalence of obesity compared with obesity defined directly from BF%. Using 40% BF as the reference standard

maximizes the indices of validity relative to a BMI cut point of 30kg/m². Furthermore, we demonstrated that whether 35%, 38% or 40% BF is used as the reference standard, a BMI cut point of 30kg/m² is too high to accurately classify women as obese or non-obese, and should potentially be replaced with BMI cut points of 24.9 kg/m², 26.5 kg/m² or 27.1 kg/m², respectively. The optimal BMI cut point to define obesity increased as the BF% to define obesity increased. This demonstrates that while BMI may not be a perfect indicator of BF%, there is still concordance between an increasing amount of body fat and an increasing BMI value. Further research is required to understand the impact of changing the cut-point for BMI-defined obesity and how it relates to health outcomes or future disease risk.

Our results are consistent with previous research demonstrating poor diagnostic accuracy of BMI in older women.^{12,32} In line with the conclusions of Evans et al. (2006) and Batsis et al. (2016), our findings suggest that using a cut point of 30 kg/m² to define obesity in postmenopausal women is too high. Using this BMI cut point results in a low true positive rate (i.e., sensitivity) and a high true negative rate (i.e., specificity). There is a well-known trade-off between sensitivity and specificity in diagnostic research; lowering the BMI cut-off value will increase sensitivity (identifying more true positives) at the cost of specificity, producing more false positives.³⁸ Thus, the cost of lowering the BMI cut point to define obesity in postmenopausal women will come in the form of more women being erroneously diagnosed as obese according to BMI, when, in fact, they are not truly obese. In making this decision, it is important to weigh the implications of keeping the cut point at 30kg/m², and potentially missing the diagnosis of true cases of obesity versus lowering the cut point and potentially misclassifying non-obese women as obese.

Our study highlights two important challenges faced by researchers and clinicians focused on obesity in postmenopausal women. Firstly, although it is evident that BMI 30kg/m² is suboptimal for classifying truly obese postmenopausal women as obese, it may be challenging to come up with a superior method to assess obesity that could realistically be implemented in busy clinical settings with limited resources. Aside from its use in research, BMI is frequently used to inform clinical decisions, such as identifying whether an individual patient is an appropriate candidate for surgery or to predict future risk of morbidity (i.e., risk of fracture, coronary disease, cancer)^{39–42}. It is unrealistic to assume that direct methods of assessing adiposity are available to or affordable for clinicians responsible for treating postmenopausal women. One potential solution is using inverse BMI (iBMI=1000/BMI, cm/kg²) to classify post-menopausal women as obese, as it has been demonstrated to be a better proxy for percent body fat and true obesity status.⁴³ The relationship between BMI and BF% is non-linear, as previously reported by other authors and indicated by the quadratic lines of best fit in Figures 1a and 1b.^{11,43,44} However, prior research has demonstrated that the relationship between iBMI and BF% is linear, indicating that iBMI may be a better predictor of true obesity status. There is currently no recognized cut point to identify obesity according to iBMI, so this represents an interesting opportunity for future research.

The second challenge raised by the present results is that if BMI is being used as a proxy to indicate true adiposity status, it is evident that 30kg/m² may not be the appropriate cut point to use to define obesity in postmenopausal women. Although BMI 30 kg/m² is widely

recognized as the cut point to define obesity, and its use is ubiquitous, the scientific rationale for using a threshold of 30 kg/m², as opposed to an alternative BMI value, such as 28 kg/m² or 29 kg/m², is relatively weak. The 1995 WHO Technical Report, responsible for initially creating the BMI categories, states “the method used to establish BMI cut-off points has been largely arbitrary. In essence it has been based on visual inspection of the relationship between BMI and mortality: the cut-off of 30 is based on the point of flexion in the curve” (p.313).⁸ The present results provide empirical evidence that it may be appropriate to re-evaluate whether the current threshold of 30kg/m² should continue to be used to define obesity in women’s health research, considering its weak validity and poor diagnostic accuracy relative to true obesity status.

Studies have documented that the effect of obesity on mortality may be attenuated in older women resulting in an apparently reduced risk of obesity-related morbidity.^{4,20} Bea and colleagues reported a consistent decrease in obesity-related mortality risk by age among women in the Women’s Health Initiative, ranging from 1.46 (95% CI: 0.90,2.36) to 1.17 (95% CI: 0.90, 1.52) to 1.02 (95% CI: 0.80, 1.30) for women with BMI 30–35 kg/m² aged 60, 60–69, and 70.¹⁶ The present results raise an interesting question about whether the attenuated effect of obesity in older women might be attributed to incorrect classification of exposure. Many women who are truly obese are being misclassified as non-obese by BMI, potentially leading to a systematic underestimation of obesity-related mortality risks in older women.

In any research study, accurate exposure measurement is crucial to producing valid and reliable effect estimates. The sensitivity, specificity, PPV and NPV values presented here can be used to adjust for BMI-related misclassification in future studies on postmenopausal women.⁴⁵ This represents an important strength and contribution of the present work. With a large sample of post-menopausal women and an analysis that considered the effect of varying values for the BF% referent standard, these results provide researchers and clinicians with important information that can be used to improve the validity of research focused on the effect of obesity in older women. Another potential avenue for future research would be to explore the validity of other BMI categories (e.g., overweight; BMI 25 kg/m²) in older women. The present study also has several limitations. Due to the small number of non-white participants, we were unable to explore whether misclassification of obesity status varied by race. The results also are only generalizable to post-menopausal women, as our sample was exclusively composed of older females.

Conclusion

This study adds to the growing body of knowledge highlighting the limitations of using BMI to define obesity.¹³ These findings represent an important addition to the literature because the body composition of postmenopausal women is distinct from pre-menopausal women or men at any stage of the life course. As life expectancies continues to rise, women are expected to spend more than a third of their lifetime beyond the menopausal transition⁶. Understanding the effect of obesity in postmenopausal older women is critical to preventing morbidity and mortality and ensuring high quality of life as women age. Though BMI is frequently used as a measure of obesity, our findings indicate that using a BMI cut point of

30 kg/m² may lead to bias in measuring the effects of obesity on health outcomes in postmenopausal women.¹¹ Our results add an important perspective focused on aging women to a growing body of literature emphasizing the shortcomings of using BMI to define obesity.

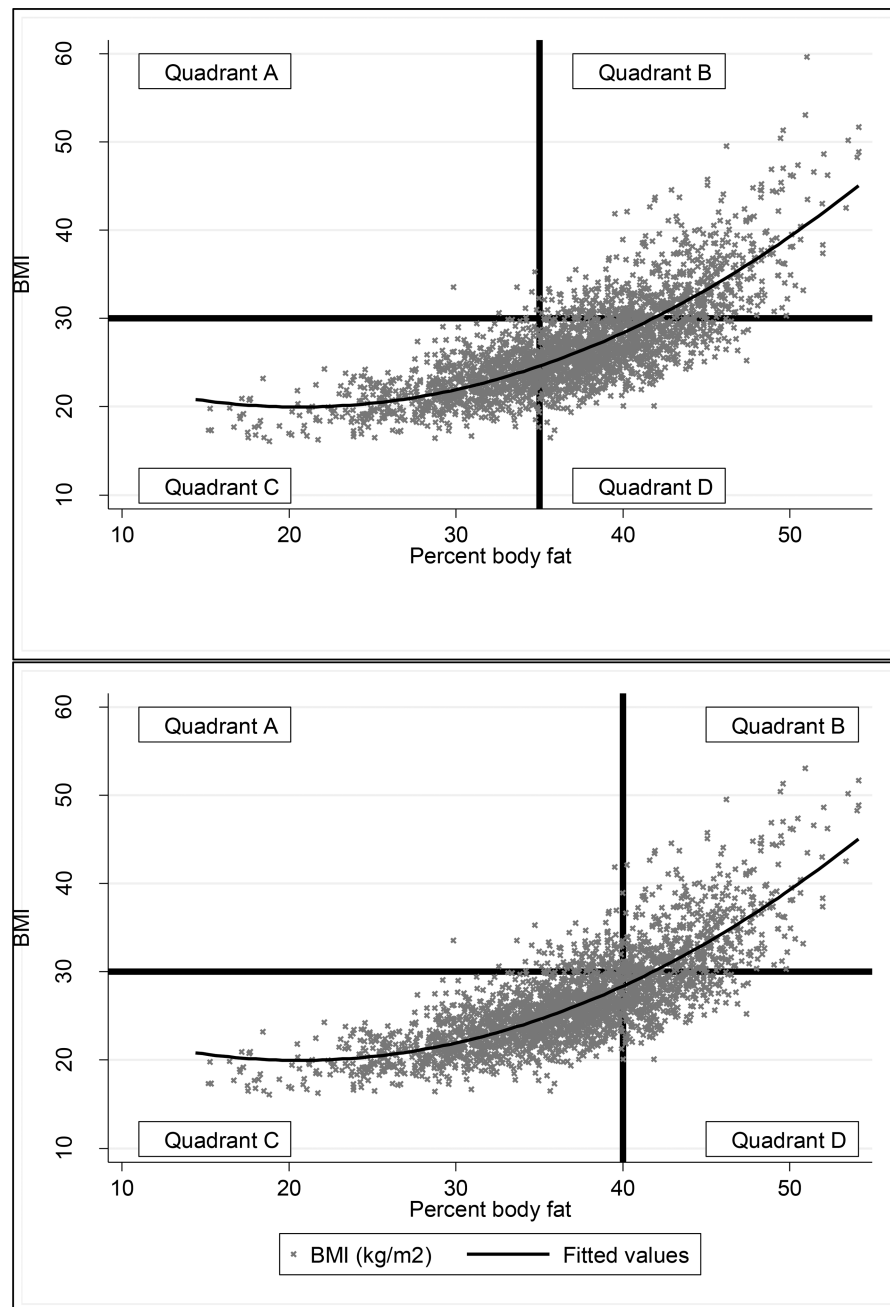

Figure 1.

a–b. Scatterplots comparing BMI (kg/m^2) with percent body fat (%). The black horizontal line represents BMI greater than 30 kg/m^2 . The curved line represents a quadratic prediction line. The vertical line indicates percent body fat greater than 35% (Figure 1a) and 40% (Figure 1b). Participants in Quadrants A and D are misclassified, participants in Quadrants B and C are correctly classified. In Figure 1a, 0.26% of women are in quadrant A, 21% are in quadrant B, 34% are in quadrant C, and 44% are in quadrant D. In figure 1b, 3.7% are in quadrant A, 18% are in quadrant B, 64% are in quadrant C, and 14% in quadrant D.

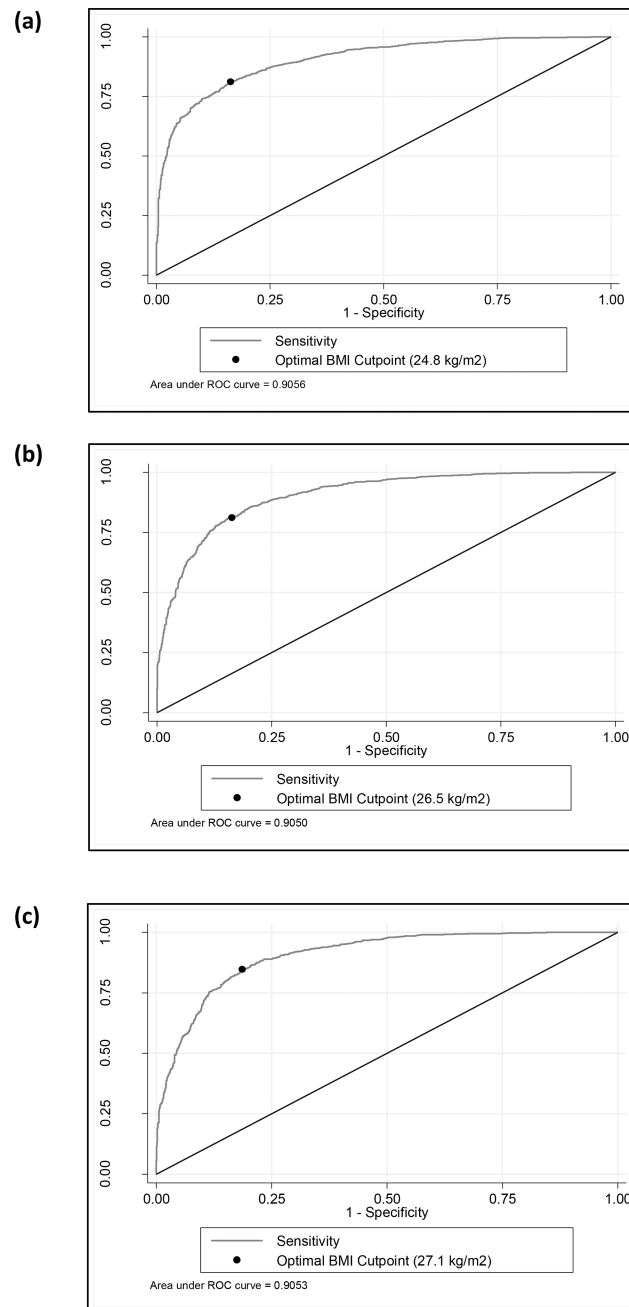

Figure 2.

a–c. Receiver operating characteristic (ROC) curves comparing BMI with a) 35%, b) 38%, and c) 40% BF cut points to define obesity. The black point on the curve of each graph demonstrates the optimal BMI threshold value for that BF% cutpoint.

Table 1

Demographic characteristics of study participants at baseline (n=1,329)

Age, mean \pm SD		66.1 \pm 7.0
Highest level of education		
	High school	280 (21.3%)
	College	585 (44.5%)
	Post-graduate	451 (34.3%)
Race		
	White	1,302 (97.6%)
	Other	35 (2.60%)
Cigarette smoking status		
	Never	705 (52.8%)
	Former	587 (43.9%)
	Current	44 (3.30%)
BMI category		
	Underweight (<18.5 kg/m²)	16 (1.20%)
	Normal weight (18.5–24.9 kg/m²)	567 (42.7%)
	Overweight (25–29.9 kg/m²)	462 (34.76%)
	Obese (>30kg/m²)	284 (21.4%)
Percent body fat (%; mean \pm SD)		36.8% \pm 6.02
Total body fat (kg; mean \pm SD)		26.8 \pm 9.20
Lean body mass (kg; mean \pm SD)		42.0 \pm 5.56
Whole body bone mineral density (g/cm²; mean \pm SD)		1.06 \pm 0.11
Hormone therapy use		
	Never	436 (32.6%)
	Former	269 (20.1%)
	Current	632 (47.3%)
Parity		
	0	168 (12.6)
	1–2	375 (28.1)
	3–4	570 (42.8)
	5	220 (16.5)
Age at menopause, mean \pm SD		49.3 \pm 5.7
Physical activity (MET-hour/week)		14.3 \pm 14.3

Table 2

Classification of obesity using BMI >30kg/m² and varying percent body fat cut-points to define obesity (N=2726)

	35% Body Fat	38% Body Fat	40% Body Fat
Prevalence of BMI >30kg/m²	66%	45%	32%
Sensitivity (95%CI)	32.4% (29.5, 35.3)	44.6% (40.9, 48.2)	55.2% (50.9 59.3)
Specificity (95%CI)	99.3% (98.6, 99.8)	97.1 (96.0, 98.1)	94.6% (93.2 95.9)
Positive predictive value (95%CI)	98.8% (97.8, 99.8)	92.5% (89.8, 95.1)	82.9% (79.0 86.8)
Negative predictive value (95%CI)	43.6 % (40.7, 46.4)	68.5% (65.9, 71.0)	81.5% (79.4, 83.6)
Percent correctly classified	55.4%	73.7%	81.8%
Area under ROC curve	0.658	0.708	0.749

Note: Details of calculation of sensitivity, specificity, positive predictive value, negative predictive value, and percent correctly classified are provided in the Supplemental Digital Content.

The optimal BMI cut point values and empirical estimates of validity at varying levels of BF%-defined obesity (N=2726)

Table 3

Cut Point	Empirical BMI optimal BMI cutpoint	Sensitivity at optimal BMI cutpoint(%)	Specificity at optimal BMI cutpoint (%)	Youden's Index (SE)	Correctly Classified (%)
TBF > 35%	24.85	0.81	0.84	0.65 (0.01)	81.9
TBF > 38%	26.49	0.81	0.85	0.66 (0.01)	82.9
TBF > 40%	27.05	0.85	0.81	0.66 (0.01)	82.5
